Abstract

A fixed scale (typically 25ms) short time spectral analysis of speech signals, which are inherently multi-scale in nature (typically vowels last for 40-80ms while stops last for 10-20ms), is clearly sub-optimal for time-frequency resolution. Based on the usual assumption that the speech signal can be modeled by a time-varying autoregressive (AR) Gaussian process, we estimate the largest piecewise quasi-stationary speech segments, based on the likelihood that a segment was generated by the same AR process. This likelihood is estimated from the Linear Prediction (LP) residual error. Each of these quasi-stationary segments is then used as an analysis window from which spectral features are extracted. Such an approach thus results in a variable scale time spectral analysis, adaptively estimating the largest possible analysis window size such that the signal remains quasi-stationary, thus the best temporal/frequency resolution tradeoff. The speech recognition experiments on the OGI Numbers95 database, show that the proposed variable-scale piecewise stationary spectral analysis based features indeed yield improved recognition accuracy in clean conditions, compared to features based on minimum cross entropy spectrum [1] as well as those based on fixed scale spectral analysis.

1. Introduction

Most of the Automatic Speech Recognition (ASR) acoustic features, such as Mel-Frequency Cepstral Coefficient (MFCC) or Perceptual Linear Prediction (PLP), are based on some sort of representation of the smoothed spectral envelope, usually estimated over fixed analysis windows of typically 20ms to 30ms of the speech signal [12]. Such analysis is based on the assumption that the speech signal can be assumed to be quasi-stationary over these segment durations. However, it is well known that the voiced speech sounds such as vowels are quasi-stationary for 40ms-80ms while, stops and plosive are time-limited by less than 20ms [12]. Therefore, it implies that the spectral analysis based on a fixed size window of 20ms-30ms has some limitations, including:

- The frequency resolution obtained for quasi-stationary segments (QSS) longer than 20ms is quite low compared to what could be obtained using larger analysis windows.
- In certain cases, the analysis window can span the transition between two QSSs, thus blurring the spectral properties of the QSSs, as well as of the transitions. Indeed, in theory, Power Spectral Density (PSD) cannot even be defined for such non stationary segments [7]. Furthermore, on a more practical note, the feature vectors extracted from such transition segments do not belong to a single unique (stationary) class and may lead to poor discrimination in a pattern recognition problem.

In this work, we make the usual assumption that the piecewise quasi-stationary segments (QSS) of the speech signal can be modeled by a Gaussian AR process of a fixed order p as in [2, 3, 9, 10]. We then formulate the problem of detecting QSSs as a Maximum Likelihood (ML) detection problem, defining a QSSs as the longest segment that has most probably been generated by the same AR process. As is well known, given a p\textsuperscript{th} order AR Gaussian QSS, the Minimum Mean Square Error (MMSE) linear prediction (LP) filter parameters \([a(1), a(2), \ldots a(p)]\) are the most “compact” representation of that QSS amongst all the p\textsuperscript{th} order all pole filters [7]. In other words, the normalized “coding error”\(^1\) is minimum amongst all the p\textsuperscript{th} order LP filters. When erroneously analyzing two distinct p\textsuperscript{th} order AR Gaussian QSSs in the same non-stationary analysis window, it can be shown that the “coding error” will then always be greater than the ones resulting of QSSs analyzed individually in stationary windows[11]. As further explained in the next sections, this forms the basis of our criteria to detect piecewise quasi-stationary segments. Once the “start” and the “end” points of a QSS are known, all the speech samples coming from this QSS are analyzed within that window, resulting in (variable-scale) acoustic vectors.

Our algorithm is thus reminiscent of the likelihood ratio test based ML segmentation algorithm derived by Brandt [9] and later on used in [10]. In [10], the author has illustrated certain speech waveforms with segmentation boundaries overlaid. The validity of their algorithm is shown by a segmentation experiment, which on an average, segments phonemes into 2.2 segments. This result is quite useful as a pre-processor for the manual transcription of speech signals. However, the author in [10] did not discuss or extend the ML segmentation algorithm as a variable-scale quasi-stationary spectral analysis technique suitable for ASR, as done in the present work.

Before proceeding further, however, we feel necessary to briefly discuss certain inconsistencies between variable-scale spectral analysis and state-of-the-art Hidden Markov models ASR using Gaussian mixture models (HMM-GMM). HMM-GMM systems typically use spectral features based on a constant window size (typically 20ms) and a constant shift size (typically 10ms). The shift size determines the Nyquist frequency of the cepstral modulation spectrum [6], which is typically measured by the delta features of the static MFCC or PLP features. In a variable-scale piecewise quasi-stationary analysis, the shift size should preferably be equal to the size of the detected QSS. Otherwise, if the shift size is x\% of the duration of the QSS, then the next detected QSS will be the same but of duration \((100 - x)\%\) and the following one will be of duration \((100 - 2x)\%\) and so on until we have shifted past the entire

\(^1\)The power of the residual signal normalized by the number of samples in the window
duration of the QSS. This results in the undesirable effect that the same QSS gets analyzed by successively smaller windows, hence increasing the variance of the feature vector of this QSS. On the other hand, the use of a shift size equal to the variable window size will change the Nyquist frequency of the cepstral modulation spectrum [6]. Therefore, the modulation frequency pass-band of the delta filters [6] will vary from frame to frame and may suffer from aliasing for shift sizes in excess of 20ms.

In [4], Atal has described a temporal decomposition technique to represent the continuous variation of the LPC parameters as a linearly weighted sum of a number of discrete elementary components. These elementary components are designed such that they have the minimum temporal spread (highly localized in time) resulting in superior coding efficiency. However, the relationship between the optimization criterion of “the minimum temporal spread” and the quasi-stationarity is not obvious. We identify the above mentioned problems and make certain engineering design choices for the fixed scale spectrum analysis. We emphasize here that this is different from the approach proposed here where we use variable size windows for the frames which were spectrally similar for sub-word unit design. We emphasize here that this is different from the usual method where we use variable window size to achieve the objective of piecewise quasi-stationary spectral analysis.

The main contribution of the present paper is to demonstrate that the variable-scale QSS spectral analysis technique can possibly improve the ASR performance as compared to the fixed scale spectrum analysis. We identify the above mentioned problems and make certain engineering design choices to overcome these problems. Moreover, we show the relationship between the maximum likelihood QSS detection algorithm and the well known spectral matching property of the LP error measure [5]. Finally, we do a comparative study of the proposed variable-scale spectrum based features and the minimum cross-entropy time-frequency distributions developed by Loughlin et al [1].

2. ML Detection of the change-point in an AR Gaussian random process

Consider an instance of a $p^{th}$ order AR Gaussian process, $x[n]$, $n \in [1,N]$ whose generative LP filter parameters can either be $A_0 = [1, a_0(1), a_0(2), \ldots a_0(p)]$ or can change from $A_1 = [1, a_1(1), a_1(2), \ldots a_1(p)]$ to $A_2 = [1, a_2(1), a_2(2), \ldots a_2(p)]$ at time $n_1$ where $n_1 \in [1,N]$. As usual, the excitation signal is assumed to be drawn from a white Gaussian process and its power can change from $\sigma = \sigma_1$ to $\sigma = \sigma_2$. The general form of the Power Spectral Density (PSD) of this signal is then known to be

$$P_x(f) = \frac{\sigma^2}{[1 - \sum_{i=1}^{p} a(i) \exp(-j2\pi if)]^2}$$

(1)

where $a(i)$s are the LPC parameters. The hypothesis test consists of:

- $H_0$: No change in the PSD of the signal $x(n)$ over all $n \in [1,N]$, LP filter parameters are $A_0$ and the excitation (residual) signal power is $\sigma_0$.
- $H_1$: Change in the PSD of the signal $x(n)$ at $n_1$, where $n_1 \in [1,N]$, LP filter parameters change from $A_1$ to $A_2$ and the excitation(residual) signal power changes from $\sigma_1$ to $\sigma_2$.

Let, $\hat{A}_0$ denote the maximum likelihood estimate (MLE) of the LP filter parameters and $\hat{\sigma}_0$ denote the MLE of the residual signal power under the hypothesis $H_0$. The MLE estimate of the filter parameters is equal to their MMSE estimate due to the Gaussian distribution assumption [2] and, hence, can be computed using the Levinson Durbin algorithm [7] without significant computational cost.

Let $x_1$ denote $[x(1), x(2), \ldots x(n_1)]$ and $x_2$ denote $[x(n_1 + 1), \ldots x(N)]$. Under hypothesis $H_1$, $(A_1, \hat{\sigma}_1)$ are the MLE of $(A_1, \sigma_1)$ estimated on $x_1$, and $(A_2, \hat{\sigma}_2)$ are the MLE of $(A_2, \sigma_2)$ estimated on $x_2$, where $x_1$ and $x_2$ have been assumed to be independent of each other. A Generalized Likelihood Ratio Test (GLRT) [11] would then pick hypothesis $H_1$ if

$$\log L(x) = \log \left( \frac{p(x_1|A_1, \hat{\sigma}_1)p(x_2|A_2, \hat{\sigma}_2)}{p(x_1|A_0, \hat{\sigma}_0)} \right) > \gamma$$

(2)

where $\gamma$ is a decision threshold that will have to be tuned on some development set. In [8], we have shown that (2) simplifies to the following.

$$\log L(x) = \frac{1}{2} \log \left( \frac{\sigma_{10}^N}{\sigma_{11}^{N-n_1}} \right)$$

(3)

In the present form, the GLRT $\log L(x)$ has now a natural interpretation. Indeed, if there is a transition point in the segment $x$ then it has, in effect, 2p degrees of freedom. Under hypothesis $H_0$, we encode $x$ using only $p$ degrees of freedom (LP parameters $A_0$) and, therefore, the coding (residual) error $\sigma_{11}^2$ will be high. However, under hypothesis $H_1$, we use 2p degrees of freedom (LP parameters $A_1$ and $A_2$) to encode $x$. Therefore, the coding (residual) errors $\sigma_{11}^2$ and $\sigma_{11}^2$ can be minimized to reach the lowest possible value. This will result in $L(x) > 1$. On the other hand, if there is no AR switching point in the segment $x$ then it can be shown that, for large $n_1$ and $N$, the coding errors are all equal ($\sigma_{11}^2 = \sigma_{11}^2 = \sigma_{11}^2$). This will result in $L(x) \approx 1$.

![Figure 1: Typical plot of the Generalized log likelihood ratio test (GLRT) for a speech segment. The sharp downward spikes in the GLRT are due to the presence of a glottal pulse at the beginning of the right analysis window (x2). The GLRT peaks around the sample 500 which marks as a strong AR model switching point](image-url)
plot the GLRT as the function of the hypothesized change over point n. Whenever, the right window i.e the segment \( x_2 \) spans the glottal pulse in the beginning of the window, the GLRT exhibits strong downward spikes which is due to the fact that the LP filter cannot predict large samples in the beginning of the window. However, these downward spikes do not influence our decision significantly as we are interested in large positive value of the GLRT to detect a model change over point. The minimum sizes of the left and the right windows are 160 and 100 samples respectively. This explains the zero value of the GLRT at the beginning and the end of the whole test segment. The GLRT peaks around sample 500 which marks a strong AR model switching point.

3. Relation of GLRT to Spectral Matching

As is well known the LP error measure possesses the spectral matching property [5]. Specifically, given a speech segment \( x \), let its power spectrum (periodogram) be denoted by \( X(e^{j\omega}) \). Let the all pole model spectrum of the segment \( x \) be denoted as \( X_0(e^{j\omega}) \). Then it can be shown that the MMSE error \( \sigma_0^2 \) of the LP filter estimated over the entire segment \( x \) is given by [5]

\[
\sigma_0^2 = \int_{-\pi}^{\pi} X(x(e^{j\omega}))d\omega \quad \text{where,}
\]

\[
X_0(x(e^{j\omega})) = \frac{1}{1 - \sum_{k=0}^{N-1} a_k(t) \exp(-j2\pi ft)}
\]

Therefore minimizing the residual error \( \sigma_0^2 \) is equivalent to the minimization of the integrated ratio of the signal power spectrum \( X(e^{j\omega}) \) to its approximation \( X_0(e^{j\omega}) \) [5]. Substituting (4) in (3) we obtain,

\[
\log L(x) = \frac{1}{2} \log \left( \frac{\int_{-\pi}^{\pi} X(e^{j\omega})d\omega}{\int_{-\pi}^{\pi} X_0(e^{j\omega})d\omega} \right)^{N-n_1}
\]

where, \( X(e^{j\omega}), X_1(e^{j\omega}) \) and \( X_0(e^{j\omega}) \) are the power spectra of the segments \( x, x_1 \) and \( x_2 \) respectively. Similarly \( X_0(e^{j\omega}) \), \( X_1(e^{j\omega}) \) and \( X_2(e^{j\omega}) \) are the MMSE \( P_{\text{MMSE}} \) order all pole model spectra estimated over the segments \( x, x_1 \) and \( x_2 \) respectively. Therefore, \( X_0(e^{j\omega}), X_1(e^{j\omega}) \) and \( X_2(e^{j\omega}) \) are the best spectral matches to their corresponding power spectra. One way of interpreting (6) is that it is a measure of the relative goodness between the best spectral match achieved by modeling \( x \) as a single QSS and the best spectral matches obtained by assuming \( x \) to consist of two distinct QSS, namely \( x_1 \) and \( x_2 \). This is further explained as follows. If \( x_1 \) and \( x_2 \) are indeed two distinct QSS, then \( X_1(e^{j\omega}) \) and \( X_2(e^{j\omega}) \) will be quite different and \( X(e^{j\omega}) \) will be a gross average of these two spectra. In other words, the frequency support of \( X(e^{j\omega}) \) will be a union of those of \( X_1(e^{j\omega}) \) and \( X_2(e^{j\omega}) \). \( X_1(e^{j\omega}) \) and \( X_2(e^{j\omega}) \), having \( p \) poles each, will match their corresponding power spectra reasonably well, resulting in a lower value of the denominator in (6). However, \( X_0(e^{j\omega}) \) will be a relatively poorer spectral match to \( X(e^{j\omega}) \) as it has only \( p \) poles to account for the wider frequency support. Therefore we incur a higher spectral mismatch by assuming \( x \) to be a single QSS when in fact it is composed of two distinct QSS \( x_1 \) and \( x_2 \). This results in the GLRT \( \log L(x) \) taking up a high value. Whereas if \( x_1 \) and \( x_2 \) are the instances of the same quasi-stationary process, then so is \( x \). Therefore \( X_1(e^{j\omega}), X_2(e^{j\omega}) \) and \( X(e^{j\omega}) \) are nearly the same with similar all-pole models, resulting in a value of the GLRT close to zero. The above discussion points out to the fact that the QSS analysis based on the proposed GLRT is constantly striving to achieve a better time varying spectral modeling of the underlying signal as compared to single fixed scale spectral analysis.

4. Experiments and Results

We have used the GLRT \( L(x) \) in (3) to perform QSS spectral analysis of speech signals for ASR applications. We initialize the algorithm with a left window size \( \nu_i \omega \) = 20ms and a right window size \( \nu_i \omega \) = 12.5ms. We compute their corresponding MMSE residuals and the MMSE residual of the union of the two windows. Then, the GLRT is computed using (3) and is compared to the threshold. The choice of the threshold \( \gamma = 3.5 \) was obtained by a visual inspection of the quasi-stationarity of the segmented speech signal as returned by the algorithm. The detected boundaries of the QSSs, using threshold \( \gamma = 3.5 \), can be found at our web-site.3 Realizing that the resulting segmentation corresponded to reasonably quasi-stationary segments, we adopted the threshold value \( \gamma = 3.5 \) for all the experiments reported in this paper. In general, the ASR results are slightly sensitive to the threshold, although not in a huge way. If the GLRT is greater than the threshold \( \gamma \), \( \nu_i \omega \) is considered the largest possible QSS and we obtain a spectral estimate using all the samples in \( \nu_i \omega \). Otherwise, \( \nu_i \omega \) is incremented by \( \text{INCR}=1.25\text{ms} \) and the whole process is repeated until GLRT exceeds \( \gamma \) or \( \nu_i \omega \) becomes equal to the maximum window size \( \nu_{\text{MAX}}=60\text{ms} \). The computation of a MFCC feature vector from a very small segment (such as 10ms) is inherently very noisy. Therefore, the minimum duration of a QSS as detected by the algorithm was constrained to be 20ms. Throughout the experiments, a fixed LP order \( p = 14 \) was used. To avoid fluctuating Nyquist frequency of the cepstral modulation spectrum[6], a fixed shift size of 12.5ms was used in the algorithm. As explained in the Section (1), this sometime resulted in the undesirable effect that the same QSS gets analyzed by progressively smaller windows. To alleviate this problem, the zerophth cepstral coefficient c(0), which is a non-linear function of the windowed signal energy and, hence, of the window size, was normalized such that its dependence on the window size is minimized.

In order to assess the effectiveness of the proposed algorithm, speech recognition experiments were conducted on the OGI Numbers corpus. This database contains spontaneously spoken free-format connected numbers over a telephone channel. The lexicon consists of 31 words. Figure (2) illustrates the distribution of the QSSs as detected by the proposed algorithm. Nearly 47% segments were analyzed with the smallest window size of 20ms and they mostly corresponded to short-time limited segments. However, voiced segments and long silences were mostly analyzed by using longer windows in the range 30ms \( \sim 60\text{ms} \). The short peak at 60ms is due to the accumulated value over all the segments that should have been longer than 60ms but were constrained by our choice of the largest window size.

Throughout the experiments, MFCC coefficients and their temporal derivatives were used as speech features. However, five feature sets were compared:

1. [39 dim. MFCC:] computed over a fixed window of length 20ms.

---

1[http://www.eurecom.fr/~tyagi/segmentation.html]
2Due to very few samples involved in the Mel-filter integration.
2. [39 dim. MFCC:] computed over a fixed window of length 50ms.
3. [78 dim. Concatenated MFCC:] a concatenation of the above two feature vectors.
4. [Minimum cross entropy,39 dim MFCC:] MFCC computed from the geometric mean of the power spectra computed from 20ms, 30ms, 40ms and 50ms long windows.
5. [Variable-scale QSS MFCC+Deltas:] For a given frame, the window size is dynamically chosen using the proposed algorithm ensuring that the windowed segment is quasi-stationary.

In [1], Loughlin et al proposed using a geometric mean of multiple spectrograms of different window sizes to overcome the time-frequency limitation of any single spectrogram. They showed that combining the information content from multiple spectrograms in form of their geometric mean, is optimal for minimizing the cross entropy between the multiple spectra. We have followed their approach to derive MFCC features from the geometric mean of the multiple power spectra computed over varying window sizes, specifically 20ms, 30ms, 40ms and 50ms.

Hidden Markov Model and Gaussian Mixture Model (HMM-GMM) based speech recognition systems were trained using public domain software HTK on the clean training set from the original Numbers corpus. The speech recognition results in clean conditions for various spectral analysis techniques are given in table 1. The fixed scale MFCC features using 20ms and 50ms long analysis windows have a 5.7% WER and it has twice the number of HMM-GMM parameters as compared to the rest of the systems\(^5\). The slight improvement in this case may be due to the multiple scale information present in this feature, albeit in an ad-hoc way. The minimum cross-entropy MFCC features which were derived from the geometric mean of the power spectra computed over 20ms, 30ms, 40ms and 50ms long analysis windows, have a WER of 5.7%. The proposed variable-scale system which adaptively chooses a window size in the range [20ms, 60ms], followed by the usual MFCC computation, has a 5.0% WER. This corresponds to a relative improvement of more than 10% over the rest of the techniques.

5. Conclusion

We have demonstrated that the variable-scale piecewise quasi-stationary spectral analysis of speech signal can possibly improve the state-of-the-art ASR. Such a technique can overcome the time-frequency resolution limitations of the fixed scale spectral analysis techniques. Comparisons were drawn with the other competing multi-scale techniques such as the minimum cross-entropy technique. The proposed technique led to the minimum WER as compared to the rest of the techniques.
