Abstract

Motivated by recent advances in computer vision research, this paper proposes a novel acoustic model called Densely Connected Residual Network (DenseRNet) for multichannel speech recognition. This combines the strength of both DenseNet and ResNet. It adopts the basic “building blocks” of ResNet with different convolutional layers, receptive field sizes and growth rates as basic components that are densely connected to form so-called denseR blocks. By concatenating the feature maps of all preceding layers as inputs, DenseRNet can not only strengthen gradient back-propagation for the vanishing-gradient problem, but also exploit multi-resolution feature maps. Preliminary experimental results on CHiME-3 have shown that DenseRNet achieves a word error rate (WER) of 7.58% on beamforming-enhanced speech with six channel real test data by cross-entropy criteria training while WER is 10.23% for the official baseline. Besides, additional experimental results are also presented to demonstrate that DenseRNet exhibits the robustness to beamforming-enhanced speech as well as near and far-field speech.

Index Terms: DenseNet, robust acoustic model, ResNet, speech recognition, CHiME-3.

1. Introduction

With the advent of deep learning techniques, the performance of automatic speech recognition (ASR) has been significantly improved. However, it is still far from satisfactory in realistic noisy and far-field scenarios. To improve robustness of ASR, microphone arrays are commonly utilized, and multi-channel speech recognition is receiving more and more attention.

Existing multichannel speech recognition system mainly consist of a frontend to improve the robustness to severe signal impairments from noise or reverberation, and a backend for acoustic modeling. Recently, the frontend has become a hot research topic. Most frontend methods rely on a model-based masking of time frequency (TF) bins to estimate signal statistics for steering a corresponding beamformer [1, 2, 3, 4, 5, 6, 7, 8, 9]. Unlike the frontend, backend acoustic modeling has received less attention. In the CHiME-3 challenge, a simple 6 layer DNN network is employed as official baseline. However, in [8], a significant performance improvement was achieved by using a Wide Residual Network (WRN) model.

In this paper, we focus on the backend acoustic modeling, and attempt to find a suitable network architecture for robust ASR. In [10, 11, 12], the multi-resolution cepstral features are demonstrated to improve recognition performance over single-resolution one under the clean or white noise situation. In [13], a WRN model is proposed, which enjoys both the advantages of deeper networks with residual architecture to alleviate the vanishing-gradient problem, and wider network settings to increase the ability to learn different kinds of features. The multichannel speech recognition system with WRN-based backend acoustic model has shown its superiority for robust ASR [8]. More recently, densely connected convolutional networks (DenseNet), which can be seen as an extension of ResNet, achieve state-of-art performance on image recognition [14, 15, 16], Semantic Segmentation [17], and Handwritten Mathematical Expression Recognition [18]. The architecture is constructed from dense blocks and pooling operations, where each dense block is an iterative concatenation of previous feature maps.

Motivated by recent advances in computer vision research, we propose a Densely Connected Residual Network, termed DenseRNet, for backend acoustic modeling in Multichannel ASR. To combine the strength of both DenseNet and ResNet, DenseRNet adopts the “building blocks” of ResNet with different convolutional layers, receptive field sizes and growth rates as basic components to be densely connected to form the so-called denseR blocks. By concatenating the feature maps of all preceding layers as inputs, DenseRNet can not only strengthen gradient back-propagation for vanishing-gradient problem, but also exploit multi-resolution feature maps. Unlike [8], DenseRNet is implemented using a fully convolutional architecture, and no Bi-directional Long Short-Term Memory (BLSTM) layer is used to model temporal sequence. To evaluate the effectiveness of DenseRNet, we conducted extensive experiments on the CHiME-3 challenge. The final DenseRNet system can achieve 7.58% in terms of word error rate (WER), which outperforms official baseline (10.23%) by a large margin.

2. Review of DenseNet and ResNet

In this section, we will briefly review ResNet and DenseNet architectures.

2.1. DenseNet: Densely connected convolutional network

DenseNet is composed of multiple dense blocks. Each block can be further divided into several densely connected convolution layers (see Fig. 1a). Each layer is defined as a basic component in a dense block, which contains composite functions of BN, rectifier non-linearity (ReLU) activation, convolution and dropout. Specifically, let \( H_l(\cdot) \) be a non-linear transformation of the \( l \)-th layer. This receives the feature maps of all preceding layers, denoted by \( x_0, x_1, \ldots, x_{l-1} \), as input

\[
x_l = H_l([x_0, x_1, \ldots, x_{l-1}])
\]

where \([\ldots]\) refers to the concatenation of all preceding layers.
According to [16], each \( H_l \) takes \( k \times (l-1) + k_0 \) input feature maps and produces \( k \)-dimensional output, where \( k_0 \) is the dimension of block input \( x_0 \), and \( k \) is referred to as the growth rate. To prevent the block growing too wide and to improve parameter efficiency, the growth rate \( k \) is practically limited to a small integer \( (k = 12) \). In addition, this \( k \) is fixed for each dense block.

Like standard CNN architectures such as VGGNet [19], the dense blocks can be connected into a network. A transition layer is further inserted between two adjacent dense blocks to change the feature map sizes. Such transition layers are composed of a 1×1 convolution followed by a 2×2 pooling operation.

### 2.2. ResNet: Residual Network

Just as in DenseNet, ResNet consists of several residual blocks. According to [20], each block is composed of multiple “building blocks”. These “building blocks” are defined as basic components in ResNet, which contain several convolution layers with a “short connection”, as shown in Fig. 1b. Specially, the output \( x_l \) of the \( l \)-th component can be expressed as

\[
x_l = F_l(x_{l-1}) + x_{l-1} \equiv H_l^r(x_{l-1})
\]

where the \( l \)-th input feature map, \( F \) is a composite of 2 or 3 non-linear transformations \( H \), and \( H_l^r \) is a residual transformation that sums the identity mapping of the input to the output. As shown in eq.(2), \( H_l^r \) allows for the reuse of features and permits the gradient to flow directly to earlier layers.

According to [20], He et al. followed the design rules of VGGNet [19], in which the width of each residual block (or the number of channels) started from 64 in the first residual block, and then increased by a factor of 2 for the remaining blocks.

In [8], Heymann et al. applied WRN as a backend acoustic model for multichannel speech recognition, and achieved a state-of-the-art performance. Compared with ResNet, DenseNet has several compelling advantages: in addition to the advantage of alleviating the vanishing-gradient problem, DenseNet can further strengthen feature propagation and exploit multi-resolution feature maps. All the above reported works motivate us to combine the strength of both DenseNet and ResNet for more powerful backend acoustic modeling. In the next section, the proposed DenseRNet will be detailed.

### 3. DenseRNet: Densely connected Residual Network

DenseRNet takes the similar hierarchical architecture of DenseNet and ResNet, which consists of multiple denseR blocks (see Fig. 1c). In this section, we first describe the structure of the denseR block, followed by the introduction of transition layers that will be inserted between denseR blocks. Then the DenseRNet-based backend acoustic model is introduced and finally, we will discuss the parameter settings for this model.

#### 3.1. denseR block

The denseR block is composed of several basic components (i.e., “building blocks” of ResNet). The basic components in a block are densely connected. Specifically, the \( l \)-th component receives the output of all preceding components, denoted as \( x_0, x_1, ...x_{l-1} \), the output can be expressed as

\[
x_l = H_l^r ([x_0, ..., x_{l-1}])
\]

where the denseR block introduces residual transformation \( H_l^r \) same as the eq.(2). As shown in Fig.1, we can see that the proposed denseR block architecture combines both dense and residual block structures. In summary, the denseR block takes the dense connection structure of the basic components, which aim to combine the advantages of both DenseNet and ResNet.

In this proposed DenseRNet model, two additional layers are used for improving the computational efficiency.

#### 3.2. Bottleneck layer

Just as in [16], an additional bottleneck layer, that is a 1×1 convolution, can be introduced before each basic component. The bottleneck layer can further reduce the number of input feature maps \([x_0, ..., x_{l-1}]\) and thus improve the computational efficiency. In practice, we set this number to be same as the growth rate \( k \).

#### 3.3. Transition layer

The transition layer is inserted into two adjacent denseR blocks to construct the DenseRNet. For speech recognition, the transition layer is designed as a composite of a 1×1 convolution layer and a pooling operation. The transition layer can further improve the model compactness by reducing the number of feature maps before feeding into the next denseR block.

Figure 1: Illustration of a) dense block, b) residual block and c) denseR block architectures.
The architecture of the DenseRNet-based backend acoustic model is shown in Fig. 2.

The input to DenseRNet is a $D \times T \times C$ tensor, where $D$ denotes the dimension of the features, $T$ is the number of frames, and $C$ are the channels. In all experiments, the 80 dimensional mean-normalized log-mel filterbank features are extracted from a given utterance. With $T$ frames in the utterance, the dimension of input tensor is thus $80 \times T$. In addition, the delta and delta-delta of the input are further exploited. The final input to DenseRNet is a $80 \times T \times 3$ tensor.

The first part of the DenseRNet is an initial convolution layer, which comprises 32 convolutions of size $7 \times 7$ with stride $2 \times 2$ followed by max-pooling with size of $2 \times 2$.

The second part of the network is composed of three denseR blocks. Following the terminology of DenseNet, each denseR block may be configured with four parameters ($L, k, (N, S)$), where $L$ is the number of basic components, $k$ the growth rate, $(N, S)$ is related to the basic component: where $N$ is the number of convolution layers and $S$ is kernel size.

The experimental results are shown in Table 1 where we list the configuration in terms of real word error rate (WER) in real test set (in %). DenseRNet is configured with parameters $(L, k, (N, S))$, where $L$ is the number of basic components, and $k$ the growth rate. $(N, S)$ is related to the basic component: where $N$ is the number of convolution layers and $S$ is kernel size.

4. Experimental evaluation

To evaluate the effectiveness of DenseRNet-based backend acoustic model, extensive experiments are conducted on the CHiME-3 dataset [21]. For fair comparison, all the frontend processing is obtained by using six channel Generalized Eigenvalue (GEV) beamformer, and the backends are trained on all six channels of noisy utterances [9].

4.1. Implementation

Our implementation for CHiME-3 follows the structure as shown in Fig. 2. The input to DenseRNet is described in section 3.4. We adopt batch normalization before each convolution and activation, following [8] and initialize the weights as in [22]. Dropout [23] with a probability of 0.5 is added across the layer except for the input and output layers. To optimize the model, we use ADAM [24] with learning rate $8 \times 10^{-4}$, and a frame-level cross entropy (CE) criterion is adopted as the objection function. The remaining experimental settings are similar to [8] and we use the Keras library for all experiments [25].

4.2. Evaluation on different parameter settings

In the following we evaluate the DenseRNet configured with different parameter settings of CHiME-3. The parameters to be evaluated includes: the growth rate $k$, the number of basic components $L$, and $(N, S)$ is the parameters of basic component.

The experimental results are shown in Table 1 where we also list the model size in Mbytes (MB). From Table. 1, we can see that when the growth rate $k$ is fixed to 24, the WER is 11.7% as (M1). While in M2, the increasing growth reduces WER 11.2%. This observation may answer Q2, in that it is not necessary to fix growth rate $k$.

From M3, we reduce $L$ to 10, and find that the performance slightly degrades to 11.6%. This may be due to the fact that the model with a configuration of smaller $L$, i.e., $L=23$ vs. $L=10$, the receptive field size is smaller. In this case, it indicates that a
network with larger receptive field size may be better, and it is unnecessary to set to a large value (Q1).

We further evaluate the effect of $N, S$, the parameters of the basic component, i.e., the number of convolution layers and $S$, the kernel size. From M4, when we increase the $N$ to 2, we find that the WER significantly reduces from 11.6% to 7.9%. This may also be attributed to the increasing receptive field size. To examine this further, we conduct the experiment with configuration $(N, S) = (1, 5)$. Results show that WER slightly degrades from 7.9% to 8.39% which means that two convolution layers can achieve 0.49% absolute reduction based on the comparable receptive field (M4). This reveals that more convolution layers in the basic component can help yield performance improvement (Q2). Since receptive field size is the same in M4 and M5, it demonstrates that the increasing network depth may have a similar effect as having a larger receptive field size. The best performance is achieved with $(N, S) = (3, 3)$, where a WER of 7.58% has been achieved in M6.

4.3. Performance comparison with different models

This experiment compares the proposed DenseRNet with other backend acoustic models, including the 6-layer DNN of the official baseline, WRBN [8] and with ResNet and DenseNet. Except for the official baseline performance, we have implemented the models using Keras[25]. The experimental results may differ slightly with the literature, mainly due to variations in frontend processing. For fair comparison, we configure the model to have the similar receptive field size, as shown in Table 2. From the table we can see that DenseRNet achieves the best performance, outperforming the official baseline by a large margin.

4.4. Experiments on robustness of DenseRNet

In this experiment, we evaluate the robustness of DenseRNet. Three kinds of speech, (i.e., CH5, Enh, CH0) from CHiME-3, are used for evaluation [21]. Results are reported in Table 3. Firstly, we can see that the performance of DenseRNet is superior to the 6-layer DNN model for all evaluations. For different evaluation conditions, DenseRNet can achieve similar performance on Enh (6.46%) and CH0 (7.90%). DenseRNet is also more robust than the baseline to beamforming-enhanced speech as well as near and far-field speech.

Fig. 3 gives further insight into the robustness of DenseRNet by analyzing the mean feature maps from one CHiME-3 real test set utterance. In the first column, which shows three different inputs, (i.e., CH5, Enh, and CH0), we see they are clearly different. From the second to the last column in the figure, which corresponds to the mean of output feature maps from the $2^{rd}$ denseR block, we can see that they tend to have similar activations. This demonstrates a certain robustness to beamforming-enhanced speech as well as near, far-field speech.

5. Conclusions

In summary, this paper proposes a novel architecture which we call DenseRNet. It adopts a similar hierarchical architecture to DenseNet and ResNet, consisting of multiple denseR blocks. To combine the strength of both DenseNet and ResNet, DenseRNet adopts the “building block” of ResNet as its basic component, densely connected in the denseR block. DenseRNet can not only strengthen gradient back-propagation for the vanishing-gradient problem, but also exploit multi-resolution feature maps. To evaluate its effectiveness, we conducted experiments using the CHiME-3 corpus with different convolutional layers, receptive field sizes and growth rates. We achieved a WER 7.58% using a DenseRNet-based acoustic model on beamforming-enhanced speech with the six channel real test data, outperforming the official baseline WER of 10.23%. Additional experimental results are demonstrate the robustness of DenseRNet to beamforming-enhanced speech as well as near and far-field speech.
